

# 15-494/694: Cognitive Robotics

Dave Touretzky

Lecture 5:

Particle Filters and  
Localization

# Outline

- Probabilistic Robotics
- Belief States
- Parametric and non-parametric representations
- Motion model
- Sensor model
- Evaluation and resampling
- Demos

# Probabilistic Robotics

- The world is uncertain:
  - Sensors are noisy and inaccurate.
  - Actuators are unreliable.
  - Other actors can affect the world.
- Embrace the uncertainty!
- How?
  - Explicitly *model* our uncertainty about sensors and actions.
  - Replace discrete states with beliefs: *probability distributions* over states.
  - Use Bayesian filtering to update our beliefs.

# Beliefs

are probability distributions

Figures from Thrun, Burgard, and Fox (2005)  
*Probabilistic Robotics*

# Some Notation

- $x_t$  = state at time  $t$
- $u_t$  = *control signal at time  $t$*
- $z_t$  = *sensor input at time  $t$*
- We don't know  $x_t$  with certainty; we have an *a priori* (before measurement) belief  $\overline{\text{bel}}(x_t)$  about it:

$$\overline{\text{bel}}(x_t) = p(x_t \mid z_{1:t-1}, u_{1:t})$$

- New sensor data  $z_t$  updates our belief, giving an *a posteriori* (after measurement) belief  $\text{bel}(x_t)$ :

$$\text{bel}(x_t) = \eta p(z_t \mid x_t) \cdot \overline{\text{bel}}(x_t)$$

# Parametric Representations (1)

- Represent a probability distribution using an analytic function described by a small number of parameters.
- Most common example: Gaussian

# Parametric Representations (2)

- Good points:
  - Compact representation: just a few numbers
    - For a Gaussian: mean  $\mu$  and variance  $\sigma^2$
  - Fast to compute
  - Nice mathematical properties
  - **Easy to sample from**
- Drawbacks:
  - May not match the data very well
  - Can give bad results if the fit is poor

# Nonparametric Representations

- No preconceived formula for the distribution.
- Instead, maintain a representation of the actual distribution, via *sampling*.
- Example: histogram
- Good points:
  - Can represent completely arbitrary distributions
- Drawbacks:
  - Requires more storage
  - Expensive to update

# Where Is The Robot?

- Parametric: the robot is at  $x=1$  with  $\sigma^2 = 0.2$
- Non-parametric: 100 samples indicating robot position.

# Where Is The Robot? (Multimodal Distribution)

- Parametric: fail (or put robot at the mean:  $x=2.5$ )
- Non-parametric: 100 samples.

# Particle Filters

- A particle filter is an efficient non-parametric representation of a distribution.
- Each particle represents a sample drawn from the distribution.
- As the distribution changes, we update the particles.
- Three kinds of updating:
  - Change the *value* the particle encodes (motion model).
  - Change the *weight* assigned to the particle (sensor model).
  - *Resample* the distribution, getting a fresh set of particles with initially equal weights.

# Bayesian Filter, part 1

- Our belief about the robot's position  $x$  at time  $t-1$  is a probability distribution  $p(x_{t-1})$ , which we represent as a set of *samples*.
- At time  $t$  the robot moves, following some control signal  $u_t$ , producing a new distribution  $p(x_t)$ .
- A *motion model* defines how our new prediction  $\overline{bel}(x_t)$  arises from applying  $u_t$ .

$$\overline{bel}(x_t) = \int p(x_t | x_{t-1}, u_t) \cdot bel(x_{t-1}) \, dx_{t-1}$$

The equation is annotated with three red boxes and arrows:

- A box labeled "a priori belief at t" points to the  $\overline{bel}(x_t)$  term on the left.
- A box labeled "motion model" points to the  $p(x_t | x_{t-1}, u_t)$  term in the integrand.
- A box labeled "a posteriori belief at t-1" points to the  $bel(x_{t-1})$  term in the integrand.

# Why Are We Integrating?

$$\overline{bel}(x_t) = \int_{x_{t-1}} \underbrace{p(x_t | x_{t-1}, u_t)}_{\substack{\text{Probability of} \\ \text{arriving at } x_t \text{ given} \\ \text{that we were} \\ \text{previously at } x_{t-1} \\ \text{and got control} \\ \text{signal } u_t.}} \cdot \underbrace{bel(x_{t-1})}_{\substack{\text{Belief that we} \\ \text{were previously} \\ \text{at location } x_{t-1}}} \underbrace{d x_{t-1}}_{\substack{\text{All} \\ \text{possible} \\ \text{previous} \\ \text{locations} \\ x_{t-1}}}$$

Integrated over all possible starting locations  $x_{t-1}$ .

# Motion Models

- Motion models express the noisiness of motion  $u_t$ .
- Typically use a simple parametric distribution.
  - Easy to sample.
- We represented the distribution  $p(x_{t-1})$  as a set of a *posteriori* samples  $\text{bel}(x_{t-1})$ . Motion gives us  $\overline{\text{bel}}(x_t)$ .
- How do we sample  $\overline{\text{bel}}(x_t)$  ?
- Solution: for each sample in  $\text{bel}(x_{t-1})$ , draw a value from the motion model's distribution and add it to the sample value.

# Motion Model $p(x_t|x_{t-1},u_t)$

Figures from Thrun, Burgard, and Fox (2005) *Probabilistic Robotics*

Moderate  
Noise Values

High  
Translational  
Uncertainty

High  
Rotational  
Uncertainty

# Robot at $t=0$ : $\text{bel}(x_0)$

# Prediction at $t=1$ : $\overline{\text{bel}}(x_1)$

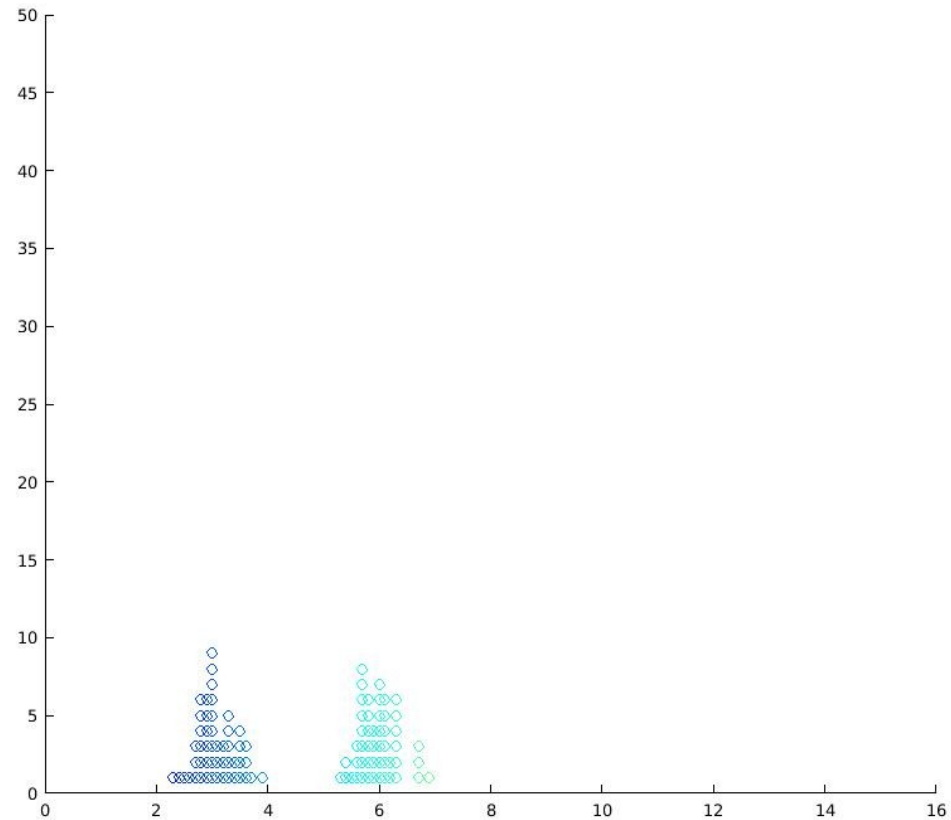

# Robot at $t=0$ : $\text{bel}(x_0)$

# Prediction at $t=1$ : $\overline{\text{bel}}(x_1)$

# Prediction at t=2: $\overline{\text{bel}}(x_2)$

# Correcting Our Prediction

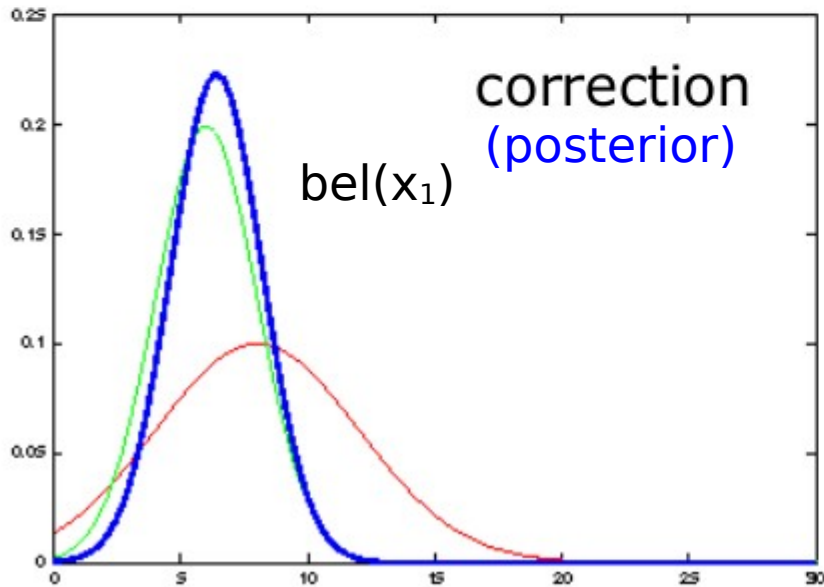

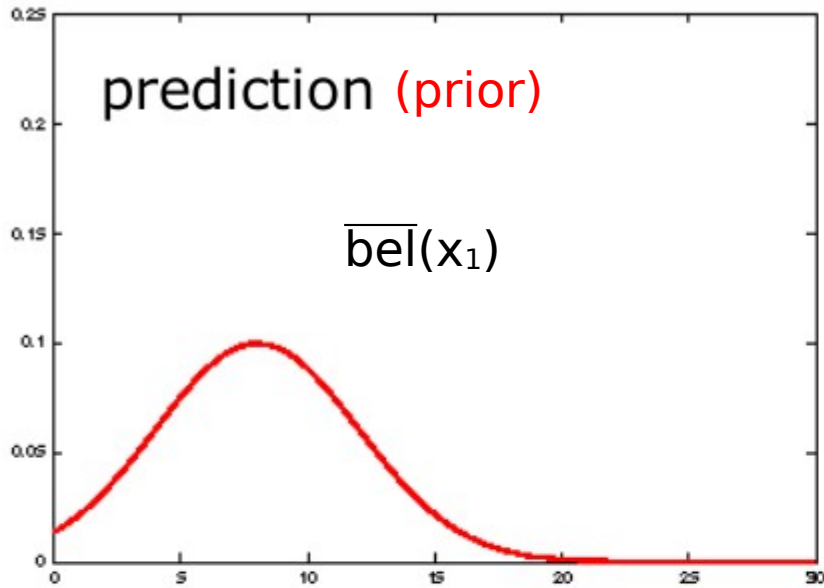

- To mitigate the noisiness of our motion model, we use sensor readings  $z_t$  to correct our belief distribution.
- Our sensors give us a probability distribution  $p(x_t|z_t)$ .
- Can't our sensors just tell us where we are?
- **NO!**
  - They're noisy.
  - An individual reading may not be that informative because the world can be ambiguous (e.g., doors look alike).
  - Need to combine prior beliefs with new information.

# Sensor Model

- We should try to model uncertainty in our sensor data.
- Lots of work on sonar and laser rangefinder noise models (e.g., effects of reflections, viewing angle, etc.)
- For visual landmarks:
  - Effects of camera resolution.
  - Distance estimates might have variance proportional to the distance value (larger distances have higher variance).
  - Bearing estimates might have variance inversely proportional to distance.

# Interlude: The Kalman Filter

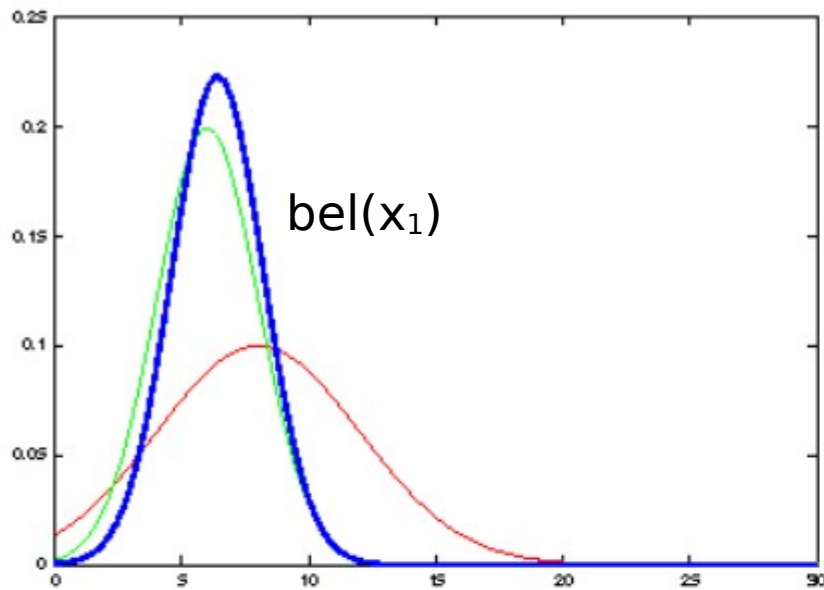

If distributions are gaussians, we can combine them using a **Kalman filter**. Weighting is inversely proportional to variance.

It's a weighted mean!

Slide modified from Burgard et al., "Introduction to Mobile Robotics", 2014, lecture 9: "Bayes Filter - Kalman Filter".

Second iteration: prior belief  $\rightarrow$  prediction  $\rightarrow$  measurement  $\rightarrow$  correction.

Slide modified from Burgard et al., "Introduction to Mobile Robotics", 2014, lecture 9: "Bayes Filter - Kalman Filter".

# Product of Two Gaussians

$$\mu_3 = \frac{\mu_1 \sigma_2 + \mu_2 \sigma_1}{\sigma_1 + \sigma_2}$$

$$\sigma_3 = \frac{\sigma_1 \cdot \sigma_2}{\sigma_1 + \sigma_2}$$

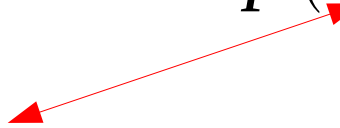

# Bayesian Filter, part 2

From part 1:

$$\bar{bel}(x_t) = \int_{x_{t-1}} p(x_t|x_{t-1}, u_t) \cdot bel(x_{t-1}) dx_{t-1}$$

Sensor reading  $z_t$  gives distribution  $p(x_t|z_t)$ .

Corrected:  $bel(x_t) = \eta p(z_t|x_t) \cdot \bar{bel}(x_t)$

$\eta$  is a normalization constant.

But How Do We Correct  
Our Beliefs If We're Using  
Particles to Represent  
the Distribution?

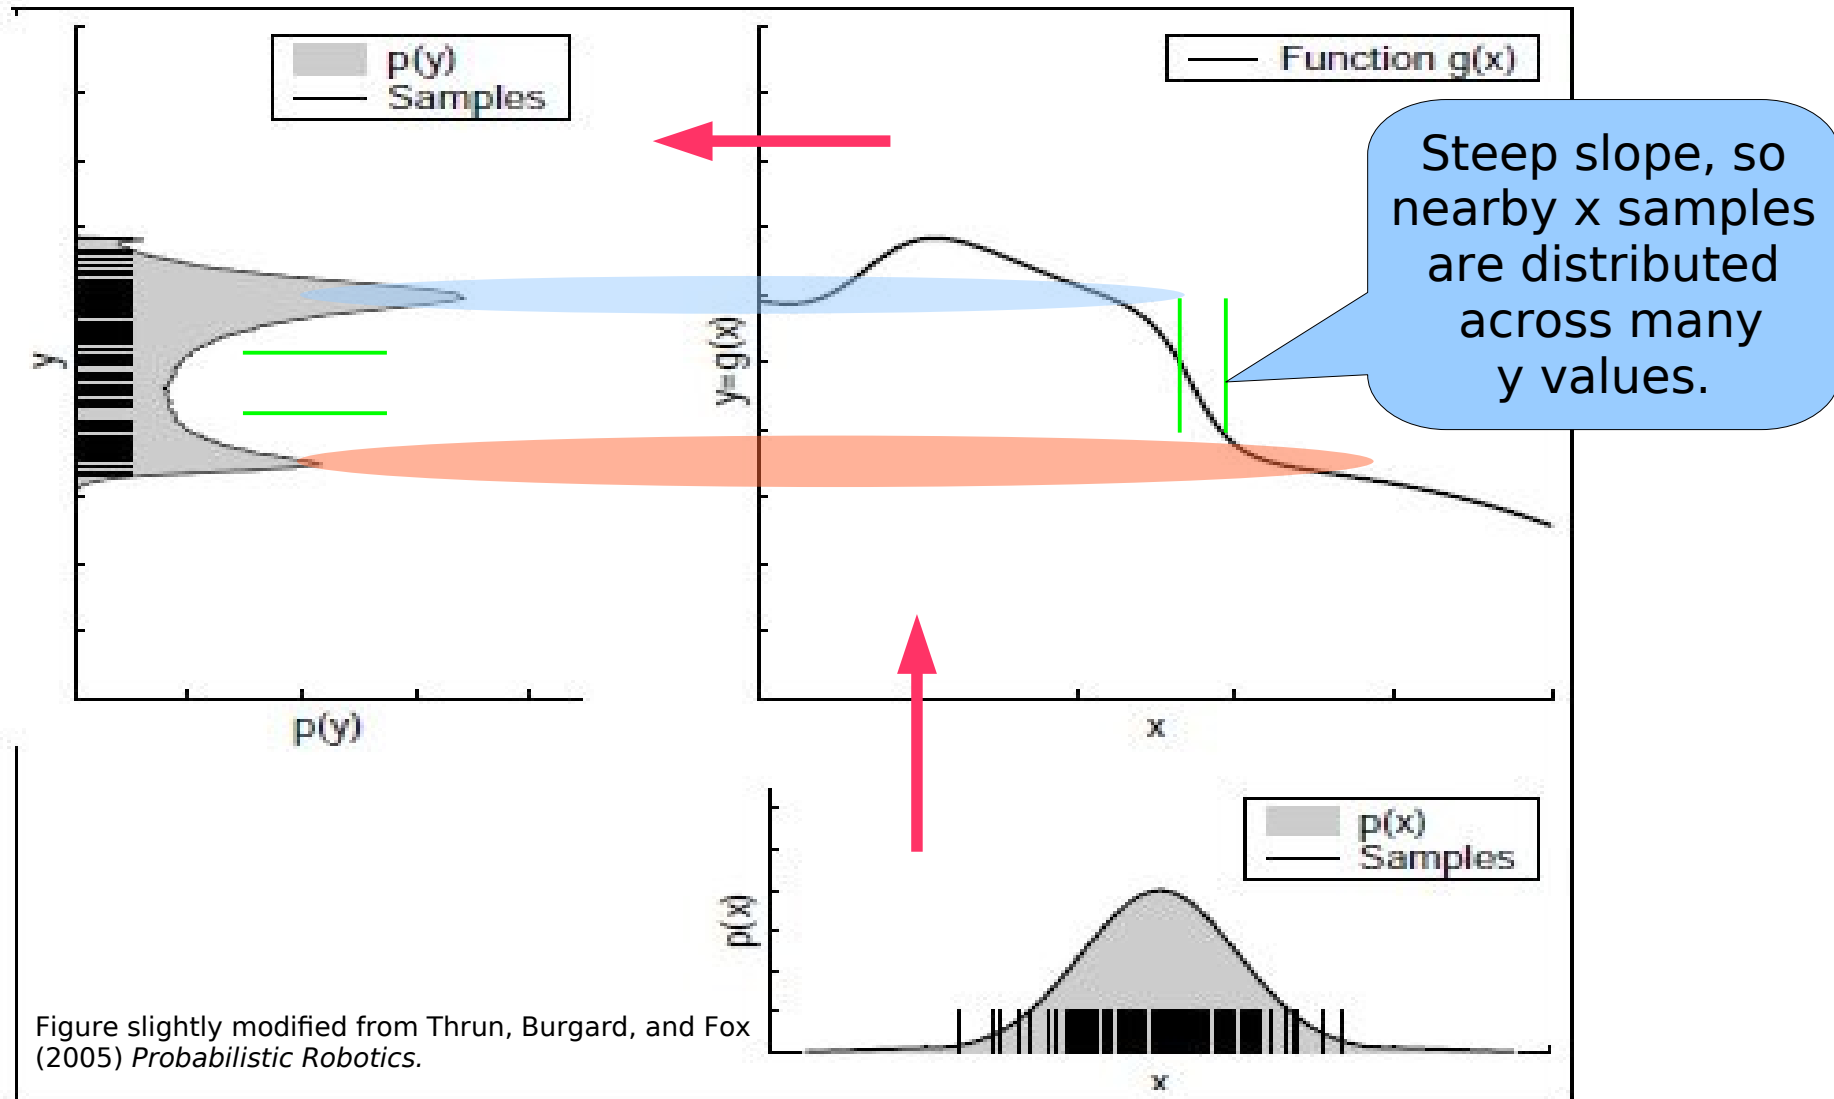

# Corrected Sampling Representation

- Prior distribution  $\overline{\text{bel}}(x_t)$  is “corrected” by weight  $p(z_t|x_t)$  to give posterior  $\text{bel}(x_t)$ .
- The *weighted* particles are a sampling representation of the new distribution  $p(x_t)$ .
- The robot can move around and we can move the particles and update their weights.
- But is this a good representation?
- Particles whose weights become low aren't representing useful hypotheses. Eventually the representation falls apart because we're sampling the wrong regions.

# Resampling

- Things break down when too many particles are representing the wrong regions of  $\text{bel}(x_t)$ , so their weights are low; they're not doing anything useful.
- We can fix this by resampling  $\text{bel}(x_t)$ , giving a fresh set of particles distributed correctly.
- But we have no formula for  $\text{bel}(x_t)$ , and no direct representation of it.
- So how do we sample from it?
  - *Importance sampling.*

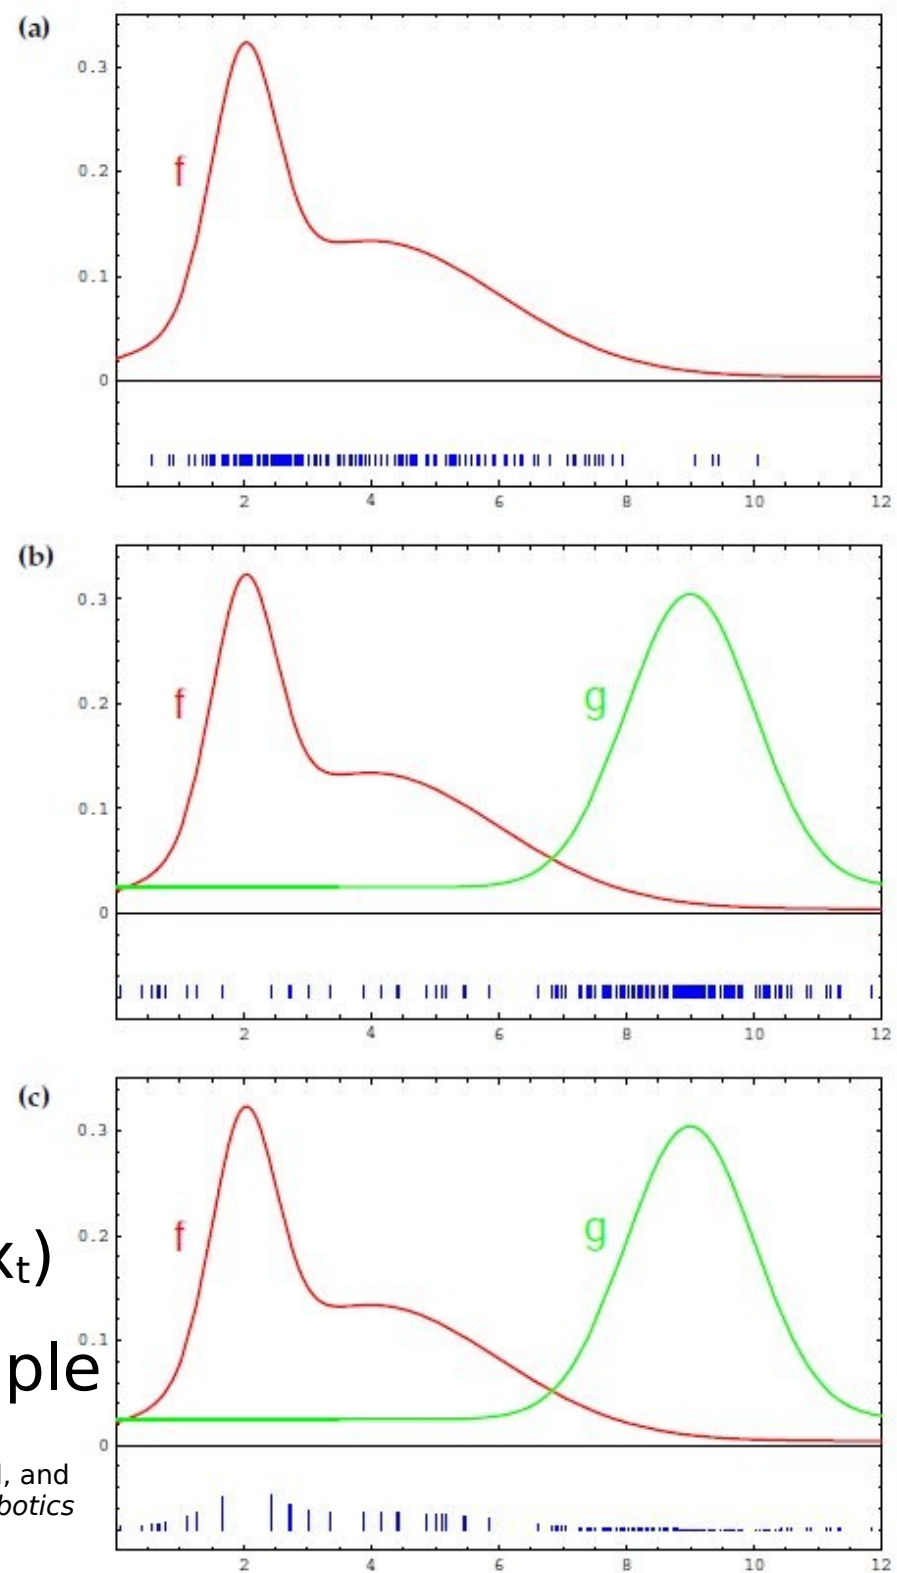

# Sampling a Function $y=g(x)$ From an Arbitrary Distribution $x$

# Importance Sampling

- Want to sample from  $f$ .
- Can only sample from  $g$ .
- Weight each sample by  $f(x) / g(x)$ .
- The weighted samples approximate  $f$ .
- $g$  is  $\overline{\text{bel}}(x_t)$
- Weighting comes from  $p(z_t|x_t)$
- Drawing from weighted sample gives  $f = \text{bel}(x_t)$

Figure from Thrun, Burgard, and Fox (2005) *Probabilistic Robotics*

# Resampling: Drawing From Weighted Samples

- We don't need to resample on every time step  $t$ . We can accumulate sensor data for several time steps, so our weights are more accurate.
- We can also use the weights to estimate the robot's location (if the distribution is unimodal):

$$\hat{x}(t) = \sum_i w_t^{(i)} \cdot x_t^{(i)}$$

- When to resample?
  - If the variance on the weights is high, then many particles are representing non-useful portions of the space.
  - Resampling redistributes the particles so they are concentrated where the probability density is highest.

# How To Resample

- Stochastic universal sampling is a trick for drawing samples from a weighted distribution as fairly as possible (**low variance sampling**).

3 samples

8 samples (equal spacing instead of independent sampling lowers the variance)

# Summary

- Particle filters are the preferred method for robot localization in the real world.
- Robot pose typically encoded as  $(x, y, \theta)$ .
- A map is needed to define how sensor values indicate locations. But what if we don't have a map?
- Particles can be used to represent hypotheses about the map as well as about the robot's location.
  - SLAM: Simultaneous Localization and Mapping.
  - We'll explore this in a later lecture.
